

1

LOAD CHANGE SAFETY SYSTEM

[0001] This invention relates to a system designed to keep the operator 30 and/or other individuals safe from the hazardous condition of a lowering stacking deck 3,3' of a sheet stacker 2,2'. The hazardous condition is the variable pinch point gap 9,9' created between the discharge end 4,4' of the stacking deck 3,3' and a conveying sheet material removal system 7,7' typically located under the discharge end 4,4' of the sheet stacker 2,2'. The conveyor system provides means for transporting material away from the sheet stacker 2,2'. The need for the load change safety system 1-1'''' is amplified by the fact that the operator 30 and/or other individuals are required to frequently go near the hazardous area of the variable pinch point gap 9,9' during normal production operation to place protective sheets, referred to as dunnage 50 and/or pallets 51 on the conveying sheet material removal system 7,7' before each sheet stack 6 is created at the discharge end 4,4' of the sheet stacker 2,2'.

[0002] The term operator 30 used throughout this patent shall be interpreted to include not only the person operating the sheet stacker 2,2' but also any and all other people that come near or in contact with the sheet stacker.

20 [0003] The term LCS system is used in this patent to refer to the Load Change Safety System.

Background of the invention

[0004] It is common to stack cardboard/corrugated sheet stacks 6 into full stacks 52, which are then conveyed in a straight line by a floor conveyor (typically top of conveyor rollers approximately 12 inches above the floor) to another machine. These full stacks 52 are often created by first placing down a pallet 51 and/or a protective sheet on said sheet material removal system 7,7'. These protective sheets are often referred to as dunnage 50 in the industry. The pallet 51 and/or dunnage 50 provides protection for the

30

1 bottom sheets of the full stacks **52** and/or allow machinery down stream
(typically fork lift trucks) to be able to handle the full stacks **52**.

[0005] One form of sheet stacker **2** found in U.S. 2,901,250 granted to Mar-
tin on August 25, 1959. The sheet stacker is typical of a class of stackers
5 referred to as "upstackers" in the industry since they create a full stack **52**
by using a stacking deck **3** which articulates in such a way that the receiving
end has little or no vertical motion and the discharge end **4** has adequate
motion to create full stacks **52** while moving in a generally upward motion.

10 The cardboard/corrugated is transported on a plurality of conveyor belts built
into the stacking deck **3** from the receiving end of the stacking deck **3** to
the discharge end **4** of the stacking deck **3**.

[0006] A second form of sheet stacker is found in U.S. 5,026,249 granted to
TEI on June 25, 1991. The sheet stacker is typical of a class of stackers re-
ferred to as a "downstackers" in the industry since they create a full stack
15 **52** by elevating and lowering the sheet material removal system **7'** under a
fixed stacking deck in such a way that the receiving end and discharge end
of a stacking deck has no motion but the elevating conveyor lowers as the
sheet stack **6** is created in order to create full stacks **52**.

[0007] A third form of sheet stacker is a hybrid where both the stacking deck
20 **2** and sheet material removal system **7'** can move in their prescribed motion
in order to create the sheet stacks **6**.

[0008] It is also common to stack cardboard/corrugated sheets into short
sheet stacks **6** referred to as bundles in the industry. The bundles are typi-
cally created at the discharge end **4,4'** of the sheet stacker **2,2'** on some
sort of conveyor roller or conveyor belt system, which is typically referred to
25 as a bundle takeaway system. Typical bundle takeaway systems are waist
high in order to allow the operator to manually manipulate the bundles down
stream.

[0009] In both situations where full stacks **52** or bundles are being created,
the sheets are stacked during the motion by which the variable pinch point

1 gap 9,9' between the discharge end 4,4' of the stacking deck 3,3' is in-
creasing. Once a full stack 52 or bundle has been created, it must be trans-
ported from under the discharge end 4,4' of the sheet stacker 2,2' . While
the full stack(s) 52 or bundle(s) is being transported, an accumulation device
5 54 is often employed to collect sheetmaterial 5 so as to allow material to
continue to fall off the end of the stacking deck 3,3' while waiting for the
full stack 52 or bundle to be transported and allowing the stacking deck 3,3'
and/or sheet material removal system 7,7' to move towards each other, thus
10 decreasing the variable pinch point gap 9,9' . One form of accumulation de-
vice 54 is found in U.S. 6,042,108, Morgan et al, granted March 28, 2000.
The variable pinch point gap must decrease in a relatively fast motion ap-
proximately 4-5 seconds on full stacks 52 and 1-2 seconds on bundles in or-
der to keep the material collecting in the accumulator area 55 from exceed-
ing the designed capacity of the accumulation device 54 . The ejecting of a
15 sheet stack and reduction of variable pinch point gap 9,9' so next sheet
stack can be built is commonly referred to as the load change cycle 56 in the
industry.

[0010] This rapid motion of the stacking deck 3 and/or sheet material re-
moval system 7' to within close proximity results in a hazardous condition
20 where the variable pinch point gap 9,9' is formed between the bottom side
of the discharge end 4,4' of the stacking deck 3,3' and the sheet material
removal system floor conveyor or bundle takeaway system. Due to the
weight and strength of the machinery, a person caught in this variable pinch
point gap 9,9' may have the result of serious injuries or death.

25 [0011] The open design of the stacking deck 3,3' is a major productivity ad-
vantage of the sheet stacker 2,2' . During normal production it is important
that the operator 50 have easy access to the discharge end 4,4' of the
stacking deck 3,3' . This invention targets the production operations per-
formed by the operator. The production operations includes setting up the

1 order, running the order, adjusting the order, checking for quality control
purposes, placing dunnage 50 and/or pallets 51 , clearing jams and placing
stack identification tags into full stacks 52 . While executing production op-
erations the operator must be able to have access to the discharge end 4,4'
5 of the stacking deck 3,3' without completely de-energizing and re-energizing
the machinery since this would have a substantial impact on production.

[0012] The maintenance/clean up operations performed by the operator 30
and other employees is a different type of operation. Unlike the production
operation where one individual is responsible for the area around the dis-
10 charge end 4,4' of the stacking deck 3,3' , the maintenance/clean up opera-
tions may involve one or more people sometimes working on key systems
including the hydraulic, pneumatic and electrical systems. Most companies
owning sheet stacking machinery have already established procedures,
commonly referred to as Zero Energy State and/or Lock-Out-Tag-Out. These
15 procedures require too much recovery time to use as a safety solution during
production operations.

[0013] The ability of the stacking deck 3 and/or sheet material removal sys-
tem 7' to be able to execute a load change cycle 56 fully automatically
without the assistance of the operator is often a required productivity feature
20 of a sheet stacker 2,2' . Prior to this invention, some sheet stacker 2,2'
owners have elected to eliminate the ability of the operator to execute a load
change cycle 56 fully automatically. These sheet stackers 2,2' may require
the operator to manually initiate the stacking deck 3,3' down motion or to
depress some sort of push button during the entire time the variable pinch
point gap 9,9' is decreasing. Even if this does not hinder the productivity
25 due to the configuration of the sheet stacker 2,2' production line, this solu-
tion still may not meet the guidelines of the International Safety Standards
which include redundancy and self-testing.

[0014] A light guard system for this type of sheet stacker 2,2' has been
available since 1990 as provided by the Geo. M. Martin Co., see Figure 1-4.
30

1 However, this system has many short comings including 1) lack of a fail-
safe mode should a single component fail, 2) no self testing, 3) difficult in-
stallation and maintenance due to stringent mirror alignment requirements, 4)
5 lack of flexibility when needing multiple mirrors to reflect the light, 5) no
fault detection of cross talk from external optical sources, 6) interference
due to light stand locations and 7) not able to run fully automatic cycling of
full stacks 52 when the sheet stacker 2,2' is equipped with an automatic
dunnage 50 and/or pallet 51 system.

10

Summary of the Invention

[0015] The Load Change Safety System 1-1'''' of the present invention is a
safety system to keep the operator 30 a safe distance from the variable
pinch point gap 9,9' while the sheet stacker 2,2' is performing the load
change cycle 56, hence achieving the very important objective of keeping
15 the operator 30 from accidentally getting near or in the variable pinch point
gap 9,9' while decreasing.

[0016] Another objective of the present invention is to provide hydraulic
redundancy by including a rigid stacking deck 3 with dual cylinders 11,12,
dual hydraulic lock valves 13,14 so that a single component failure in the
20 hydraulic system will not allow the stacking deck 3 to initiate or continue the
deck down cycle.

[0017] A further objective of the present invention is to provide the ability to
perform self- testing on the hydraulic system by adding feedback sensors
18,19 to allow detection of a hydraulic leak and/or failure.

[0018] A further objective of the present invention is to provide a robust light
25 guard system 27 by using a series of optical repeating nodes 24 instead of
mirrors to reduce the requirements for precise alignment and the accumula-
tion of accuracy error when needing to create a light guard perimeter 21 in
which the beam(s) of light must be redirected multiple times. This light guard
system 27 may be operatively connected to the LCS system control means

30

1 15'',15''' and the hydraulic lock valves 13,14 to place both valves in a state
which does not allow the variable pinch point gap 9,9' to decrease.

[0019] A further objective of the present invention is to define a configura-
tion of a light guard system 27 by which the optical repeating node 24' on
5 the operator side of the sheet stacker 2,2' near the discharge end 4,4' of
the stacking deck 3,3' is part of a movable remote control mean 35 in order
to reduce the interference that would be caused if a floor mounted optical
repeating node 24 was located in the same general proximity.

10 [0020] A further objective of the present invention is to modulate optical sig-
nals on the light beams 20,20' of the light guard system 27 in order to sub-
stantially increase the likelihood that any failure in the electrical and/or opti-
cal circuit is interpreted as a light guard system 27 intrusion and results in a
fail-safe mode.

[0021] A further objective of the present invention is to configure the rela-
15 tionship between the sheet stacker 2,2' , sheet material removal system 7,
7' and the location where the light guard perimeter 21 crosses over the
sheet material removal system 7, 7' in such a manner to allow synchronized
discharge of the full stacks 52 and fully automatic completion of the load
change cycle 56 .

1 **Description of the Invention**

[0062] In the present invention, a load change safety system 1-1''' is provided for a sheet stacker 2,2' in which a variable pinch point gap 9,9' is created during the load change cycle 56 due to the motion of the stacking deck 3,3' and/or the conveying sheet material removal system 7,7'. The variable pinch point gap 9 can be created with an "upstacker" type of sheet stacker 2 where the stacking deck 3 moves in a generally upward direction, while the conveying sheet removal system 7 remains fixed, as illustrated in Figures 5, 6, 7 & 8. Alternatively, the variable pinch point gap 9' can be created with a "downstacker" type of sheet stacker 2' where the stacking deck 3' remains fixed, while the conveying sheet removal system moves in a generally downward direction, as illustrated in Figures 9, 10, 11 & 12.

[0063] The sheet stacks 6 are first created as the sheet material 5 exits the discharge end 4,4' of the stacking deck 3,3' and the variable pinch point gap 9,9' increases. This increase in said variable pinch point gap keeps the relative distance between the elevation at which the sheet material 5 exits the discharge end 4,4' of the stacking deck 3,3' and top of the sheet stack 6 approximately the same while the height of the sheet stack 6 increases. Once the sheet stack 6 has been created, it is necessary to perform a load change cycle 56.

[0064] The load change cycle 56, illustrated in Figure 13 first requires load ejection cycle 56' in which the sheet stack 6' is transported downstream on the conveying sheet material removal system 7,7' using rollers 57 or belts. Often, during this period an accumulation device 54 is used to allow the sheet material 5 to continue to exit the discharge end 4,4' and the stacking deck 3,3'. After the load ejection cycle 56' is the deck down cycle 56'' in which the variable pinch point gap 9,9' is decreased by motion of the stacking deck 3 down and/or motion of the conveying sheet material removal system 7' up. Once the deck down cycle 56'' is completed, the accumulation device 54 retracts transferring the beginning of the next sheet stack 6'' from

1 the accumulation area **55** to the receiving means **8,8'** of the conveying sheet material removal system **7,7'**.

[0065] In the present invention, redundant means **10** including, e.g., hydraulic cylinders **11,12** , valves **13,14** and LCS system control means **15** as
5 shown in Figures 17,18, and 20, are provided to selectively prevent the decrease of the variable pinch point gap **9,9'** to reduce the chances of an operator **30** being hurt.

[0066] An upstacking sheet stacker **2** has a variable pinch point gap **9** which
10 decreases as shown by two positions, first in Figure 6 and then in Figure 8. This is due to gravities affect on the moveable stacking deck **3** . Figures 14 & 15 show two different perspective views of a typical upstacker stacking deck **3** . In this preferred embodiment, you will note the rear deck **58** is constructed using side wall members **59, 59'** and cross torque tubes **60, 60'** such that the box frame created forms a planer surface **61** . Since the cross
15 torque tubes **60, 60'** are able to resist torque, typically made from rectangular tubing, the rear deck **58** is a substantially rigid structure that attempts to keep planer surface **61** flat when rigidly pinned for pivoting by swing arms **62, 62'**. The four bar linkage created by the rear deck **58** , swing arms **62,62'**, the stacker base **63** and lifting arms **64, 64'** creates a nearly straight
20 vertical motion at the discharge end **4** of the stacking deck **3** when the lifting arms **64,64'** are operably connected to support hydraulic cylinders **11,12** . In Figures 14 & 15 the side casting **65** opposite **65'** has been removed for clarity but may be seen in Figure 18. The hydraulic cylinders **11, 12** provide redundant support, due to the existence of the substantially rigid structure created by the rear deck **58** and the fact that either hydraulic cylinder **11** or **12**
25 is capable of supporting the weight of the entire stacking deck **3**. Should either cylinder fail to provide support, the deck will 'rack' slightly as the planer surface **61** warps slightly, but the deck does not come down substantially.

[0067] In Figure 16 & 17 are detail side views of the sheet stacker **2** when
viewed from line 16-16 of Figure 15. It shows the left side casting **65'** , left
30

1 stacker lifting arm **64'** and left hydraulic cylinder **12** connecting stacker base
frame **63'** to left stacker lifting arm **64'**. If oil flows into left hydraulic cylinder
port **66** , the left hydraulic cylinders **12** rod extends **94** increasing the
variable pinch point gap **9**. Likewise, due to gravity, oil is naturally pressur-
5 ized at all time to flow out of left hydraulic cylinder port **66**. Connected to
left hydraulic cylinder port **66** is first a left hydraulic velocity fuse **68**. The
left hydraulic velocity fuse **68** has a feature of locking up and stopping oil
from exiting left hydraulic cylinder port **66** should the flow rate exceed a cer-
10 tain designed threshold; typically to keep a hydraulic line blowout from caus-
ing damage. While not required for the present invention, including a
hydraulic velocity fuse **67, 68** on each cylinder is considered good practice.
Then, connected to the left hydraulic velocity fuse **68** is hydraulic lock valve
14 which will let oil into hydraulic cylinders **12** via check valve but will only
let oil out of hydraulic cylinder port **66** only if hydraulic lock valve solenoid
15 **70** is energized. There is a separate and independent right hydraulics lock
valve **13** connected in a redundant fashion to right hydraulic cylinders **11**.
The result is two independent and redundant support means or systems **10** ,
with both right hydraulic lock valve solenoid **69** and left hydraulic lock valve
solenoid **70** needing to be activated in order to allow a narrowing of variable
20 pinch point gap **9** .

[0068] The LCS system control means **15** shown in fig 20 allows the opera-
tor **30** to press a deck down enabled button **71** in order to electrically acti-
vate redundant hydraulic lock valve solenoids **69, 70** . Said deck down en-
abled button **71** has redundant right and left deck down enabled contacts
72, 73 that will conduct electrical power down redundant paths to self test-
25 ing means **74,75** which then may conduct to fault detection means **76, 77**.
The order of these paths are not important. In the simplest form, the redun-
dant LCS system control means **15** would not have self-testing means **74,75**
nor fault detection means **76,77**. However, in the preferred embodiment,

1 these elements are added to even further reduce the likelihood of an unsafe condition.

[0069] In the simplest form, the operator 30 would press the deck down enabled button 71 which is positioned such that the operator 30 is a safe distance from the variable pinch point gap 9 . If the operator releases the deck down enabled button 71 both redundant paths would provide support to the stacking deck. However, should a single component fail on either redundant path, the variable pinch point gap 9 would still stop decreasing.

5 [0070] A downstacking sheet stacker 2' has a variable pinch point gap 9' which decreases as shown by two positions; first in Figure 10 and then in Figure 12. This is due to the raising of the conveying sheet material removal system 7' . Unlike an upstacker, see Figure 6, in which gravity naturally tries to decrease the variable pinch point gap 9 , with a downstacking sheet stacker 2' , gravity is naturally trying to increase the variable pinch point gap 15 9' , see Figure 10. As a result, redundancy can be achieved by using only one hydraulic cylinder 11' or more than one hydraulic cylinders 11' , 12' . A mechanical failure of the hydraulic cylinder 11' can not cause the variable pinch point gap 9' to decrease. In typical embodiments, there are a plurality of cylinders due to mechanical engineering requirements.

20 [0071] This invention could be applied to the variable point point gap (101') that may exist between the bottom side of the conveying sheet material removal system (7') and the floor. However, in the interest of brevity, this will not be described in detail

[0072] The redundancy means 10' involves using a plurality of hydraulic lock valves 13' , 14' in a redundant LCS system control means 15' shown in Figure 21. By placing the hydraulic lock valves 13' , 14' in series, they both 25 must be actuated and functioning normally in order to allow pressurized oil to flow into one or more than one hydraulic cylinders 11' , 12' , which in turn decreases the variable pinch point gap 9'.

1 [0073] The LCS system control means 15' shown in Figure 21 allows the
operator 30 to press a deck down enabled button 71 in order to electrically
activate redundant hydraulic lock valve solenoids 69', 70'. Said deck down
enabled button 71 has redundant right and left deck down enabled contacts
5 72, 73 that will conduct electrical power down redundant right and left
paths to self testing means 74', 75' which then may conduct to redundant
right and left fault detection means 76', 77'. The order of these paths are
not important. In the simplest form, the redundant LCS system control
10 means 15' would not have self testing means 74', 75' nor fault detection
means 76', 77'. However, in the preferred embodiment, these elements are
added to even further reduce the likelihood of an unsafe condition.

[0074] In the simplest form, the operator 30 would press the deck down en-
abled button 71 which is positioned such that the operator 30 is a safe dis-
tance from the variable pinch point gap 9'. If the operator releases the deck
15 down enabled button 71 both redundant paths would provide support to the
stacking deck. However, should a single component fail on either redundant
path, the variable pinch point gap 9' would still stop decreasing.

[0075] Both LCS system control means 15, 15' use feedback from various
sensor means 17, 17' in order to detect if a condition exists that requires
20 making sure no power flows to redundant hydraulic lock valve solenoids 69,
70, 69', 70'. Some of these conditions are classified as self-testing in na-
ture while others are considered to be faults.

[0076] Sensor means 17, 17' include hydraulic position sensor 18, 18',
which is activated in one state at a predefined raised position of an associ-
ated hydraulic cylinder 11, 12. Should a failure of support occur in one of
25 the hydraulic cylinders, the associated hydraulic position sensor 18, 18' will
activate to a different state.

[0077] Sensor means 17 may also include the deck down enabled button 71,
which can be monitored to determine if redundant contacts are synchronized
and how long they have been in either state.

- 1 [0078] Sensor means 17 may also include the operator in position sensor 47,
which can be monitored to determine if its output changes and how long it
has been in either state. The operator in position sensor 47 is mounted on
remote control means 35 operably connected to said sheet stacker 2 or 2' .
- 5 The LCS system control means 15,15' monitors said operator in position
sensor 47 to make sure the operator is a safe distance from the variable
pinch point gap 9,9' while decreasing.
- [0079] Sensor means 17 may also include the boom in position sensor 48,
10 which can be monitored to determine if its output changes. Since the re-
mote control means 35 is swivelly attached to or adjacent to said sheet
stacker 2, 2', in the preferred embodiment, the boom in position sensor 48
makes sure the boom is in the position shown in Figure 35 as opposed to the
location shown in Figure 36. This assures that the operator 30 has a good
sightline to the area near the variable pinch point gap 9,9'.
- 15 [0080] Logic means for self testing 78,78' include but are not limited to: 1)
periodic testing the load change hydraulic system 49,49' integrity, 2) proper
functioning deck down enabled button 71, 3) proper functioning of boom in
position sensor 48 and 4) proper functioning of operator in position sensor
47. If the self-testing conditions are not met, the self-testing contact chain
20 80,81,80',81' will not allow power to flow to hydraulic lock valve sole-
noid(s) 69,70,69',70'.
- [0081] Logic means for fault detection 79, 79' include but are not limited to:
1) redundant hydraulic lock valve solenoids not being synchronized in the on
or off state, 2) the deck down enabled button 71 being active for too long of
a period and 3) the operator in position sensor 47 being active for too long of
25 a period. If a fault condition is detected, the fault contact chain
82,83,82',83' will not allow power to flow to hydraulic lock valve sole-
noid(s) 69,70,69',70'.
- [0082] The basic form of redundant means 10,10' for keeping the operator a
safe distance from the variable pinch point gap 9,9' requires that the opera-

1 tor 30 holds down the deck down enabled button 71 anytime the variable
pinch point gap 9,9' is decreasing. However, there are production line con-
figurations where this is not practical or economical. For instance, in a bun-
dling application where the sheet stacks 6 are built short to form bundles,
5 not shown, the cycle time of the discharge end 4 the stacking deck 3 can be
so short that the operator 30 would end up spending nearly all his/her time
holding the deck down enabled button 71 .

[0083] In order to solve this problem, the present invention includes an elec-
10 tro-optical light guard means 27 , see Figure 22, that is activated by the op-
erator 30 from outside the light guard perimeter 21 after the operator 30
first visually checks to make sure the area within the light guard perimeter
21 is clear of other personnel and then presses a light guard activation but-
ton in order to latch the light guard control circuit 85 to an active state. The
term latch indicates that the light guard control circuit 85 will remain active
15 until another event, such as the light guard perimeter 21 being crossed or
loss of power to sheet stacker 2,2' should occur. Thus, after activating the
light guard control circuit 85, the operator 30 may walk away from light
guard activation button, leaving the redundant means 10, 10' in a state al-
lowing a decrease in variable pinch point gap 9,9'. The light guard activation
20 button is operably connected to the deck down enabled button 71 in the pre-
ferred embodiment. This light guard control circuit 85 is operably connected
to the light guarded LCS system control means 15'',15''' which operably
controls the redundant means 10, 10' for selectively preventing a decrease
in variable pinch point gap 9,9'.

[0084] The light guard perimeter 21 is constructed by using one or more light
25 beam (s) 20,20' that must be redirected multiple times in order to create the
appropriate perimeter around portions of the sheet stacker 2, 2' and portions
of the conveying sheet material removal system 7,7' such that when an op-
erator 30 or other person should break the light guard perimeter 21, the re-
dundant means 10,10' can prohibit a decrease in variable pinch point gap

1 **9,9'**. Each light beam circuit starts with a light beam transmitter **22** that converts an electrical signal into an optical signal. The redirection is accomplished using an optical repeating node **24,24'**, as illustrated in Figure 24. Unlike conventional mirrors used to redirect the light beam, the optical repeating node (s) **24,24'** uses a repeater pair **28** which consist of an repeater optical receiver **25** which is aligned in the general direction of the incoming light beam **20** . The repeater optical transmitter **26** is electronically connected by repeater circuitry **29** to its associated repeater optical receiver **25**
5 such that the optical signal received by the repeater pair transmitted at the new redirected angle by the repeater optical transmitter **26**. The repeater circuitry **29** needs to meet the electrical engineering requirements of the selected electro-optical components, but in the preferred embodiment, the repeater circuitry **29** does not include any sophisticated clock base electronics, such as micro-controllers or other crystal based components. This is to as-
10 sure that an optical data signal initiated by the light beam transmitter **22** can only be repeated and received by light beam receiver **23** by properly functioning repeater pair(s).

[0085] The advantage of using the optical repeating node(s) **24,24'** instead of using reflective mirrors **89-89'''** is illustrated in Figures 25 – 30. In Figure
20 **25**, a scaled version of a sheet stacker **2** was drawn in planned view, using AutoCAD with a light guard perimeter **21''** created using a light beam transmitter **22''** , a series of mirrors **89-89'''** at stations **86, 86', 86'', 86'''** and a light beam receiver **23''** at station **86''''**. A dimension of 120 inches has been added to Figure to give the drawing scale. By applying the basic physics of light where the angle of incidence equals the angle of reflection, a per-
25 fectly aligned light guard perimeter **21''** was created using light guard beam **87**. Then, in order to show how sensitive a reflective mirror system is to misalignment, the mirror at the first station **86**, which is assumed to be 4 inches in size, see Figure 26, is misaligned by approximately 0.010 inches. This correlates to an angular misdirection of approximately 0.3 degrees.

- 18 - **EL 967 94 7731**

1 Then, assuming all the other mirrors **89'-89'''** remain in perfect alignment, which is quite an assumption in heavy industry, the light beam is redrawn as misaligned light guard beam **88**, again using the basic law of reflection. As shown in Figure 26, the angle of reflect is off by approximately 0.3 degrees.

5 In Figure 27, when the light rays arrive at station **86'**, the misaligned light guard beam **88** is off by $2 \frac{3}{8}$ inches. At station **86''**, in Figure 28, the misaligned light guard beam **88** is off by $4 \frac{1}{16}$ inches. At station **86'''**, in Figure 29, you would now need over a 20 inch mirror, since the misaligned

10 light guard beam **88** is over 10 inches off center line. By the time the misaligned light guard beam **88** gets to the light beam receiver **23''** in Figure 30, it is off by over 4 inches. In addition to this tremendous sensitivity to angular misalignment, a reflective mirror system also has the poor characteristic of accumulating misalignment error. That is, if the mirrors **89'**, **89''** at station **86'** and **86''** both have a misalignment, the error would add to each

15 other.

[0086] The optical repeating system of the present invention essentially uses a transmitter and receiver to create each straight section of the light guard perimeter **21**. Since the preferred optical transmitters generates a cone of light, the preferred optical receiver has a lens to allow for rays of light to enter to a certain amount of angular misalignment, an angular misalignment of 20 3 degrees or more are easily achieved. In addition to the 10 times or more forgiveness to misalignment, the optical repeating system does not accumulate misalignment error. By referring to Figure 24, it is clear that any misalignment of the rays of beam coming into repeater optical receiver **25** has no impact on the alignment of repeater optical transmitter **26**. The only disadvantage of the optical repeating system compared to the reflective mirror system is the fact that the repeating nodes typically require an external power supply.

[0087] In the preferred embodiment, the light guard means **27**, includes two light beam **20,20'** circuits, separated vertically as shown in Figure 23. The

30

1 number of light beams, their vertical locations and the distance of the light
beams from the variable pinch point gap 9,9' are based on using safety
standards as a guideline and computer simulated biomechanical analysis of
trip scenarios.. When using two beams, it is preferred to have the top beam
5 20 and the bottom beam 20' ±s12v1P directed in opposite direction, to further elimi-
nate the possibility of cross talk between the two beams.

[0088] A load change safety system 1" of the present invention for a sheet
upstacker 2 having a stacking deck 3, formed with a discharge end 4, for
10 discharging sheet material 5 onto and building a sheet stack(s) 6 on a con-
veying sheet material removal system 7, formed with a receiving means 8
may consist of the following elements.

[0089] In such systems, a variable pinch point gap 9 is formed by relative
motion between the discharge end 4 of the stacking deck 3 of the sheet
stacker 2 and the receiving means 8 of the conveying sheet material removal
15 system 7. In the present invention, redundant means 10 is provided for se-
lectively preventing a decrease in the variable pinch point gap 9.

[0090] To guard personnel from this pinch point gap 9, an electro-optical
light guard means 27 is operably connected to the redundant means 10 with
one or more redirections of one or more light beams 20 to create a light
20 guard perimeter 21 for guarding portions of the sheet stacker 2 and portions
of the conveying sheet material removal system 7.

[0091] The electro-optical light guard means 27 includes one or more light
beam transmitters 22 and one or more light beam receivers 23. The electro-
optical light guard means 27 further includes one or more optical repeating
nodes 24 or 24' using an optical receiver 25 and an optical transmitter 26
25 for creating the redirection of the light beam(s) 20.

[0092] The redundant means 10 also includes a plurality of hydraulic cylin-
ders 11 and 12 for raising and lowering the stacking deck 3. The hydraulic
cylinders 11 and 12 must be of adequate strength such that should one cyl-

1 inder 11 or 12 fail to provide a support for the stacking deck 3, the remain-
ing cylinder 11 or 12 can support the weight of the stacking deck 3.

5 [0093] A plurality of valves 13 and 14 are provided wherein at least one
valve 13 or 14 is independently connected to each of the cylinders 11 and
12 which may selectively and alternatively permit and prevent flow of fluid
from those of the hydraulic cylinders 11 and 12 which are operating normally
and have not failed, thereby resulting in rapidly preventing the variable pinch
point gap 9 from narrowing.

10 [0094] A light guard control means 15'' is operatively connected to the elec-
tro-optical light guard means 27 and operatively and independently con-
nected to each of the valves 13 and 14 for alternatively permitting and pre-
venting flow of fluid from the hydraulic cylinders 11 and 12.

The load change safety system 1''' for a down stacker system is nearly iden-
tical to the load change safety system 1'' for an upstacker system as de-
15 scribed immediately above, but with the following changes.

[0095] The redundant means 10' include one or more hydraulic cylinders 11',
12' for raising and lowering an elevating platform 16' of the conveying sheet
material removal system 7' instead of being mounted on the upstacker 2.

[0096] Further, while only a single cylinder is required for raising the platform
20 16', generally two or more cylinders are provided for other reasons. In such
systems, a plurality of valves 13' and 14' are provided wherein the valves
13' and 14' are operatively connected to each other and the cylinders 11'
and 12' by means such that all of the valves 13' and 14' must simultane-
ously be activated and operate normally for selectively and alternatively per-
mitting and preventing flow into the hydraulic cylinders 11' and 12' which
25 are operating normally and have not failed, thereby preventing the variable
pinch point gap 9' from narrowing.

[0097] In the present invention the pinch point gap 9' is protected by a light
guard control means 15''' operatively connected to the electro-optical light
guard means 27 and operatively and independently connected to each of the
30

1 valves **13'** and **14'** for alternatively permitting and preventing flow of fluid into the hydraulic cylinders **11',12'**.

[0098] Since any electro-optical component can fail and the failure can result in a sensor output in the on or off state, the electro-optical light guard means
5 **27** requires a modulated signal detection means **34** such that a failure of an electro-optical component in either state will send the same light guard output signal as if the light guard perimeter **21** is blocked. A modulated transmitter circuit is connected to the light beam transmitter(s) **22** such that the
10 modulated signal detection means **34** can generate a defined modulated optical signal **33** in series around the light guard perimeter **21** via optical repeating nodes **24,24'**. A receiver decoding circuit **31** feeds back to the modulated signal detection means **34** the electrical equivalent of the defined modulated optical signal **33**. The modulated signal detection means **34** can determine if the modulated signal has been properly received. Since the sig-
15 nal must be modulated, a failure of any electro-optical component in either the on or off state can be interpreted as a blocked light guard perimeter **21** and the associated signal sent as the light guard output signal **43**. Of course, an actual blockage of the light guard perimeter will generate the proper signal sent as the light guard output signal **43**.

20 [0099] The light guard output signal **43** is operably connected to light guarded LCS system control means **15'', 15'''**. When the light guard output signal **43** indicates a blockage of the light guard perimeter **21**, the associated light guard control circuit **85** will be deactivated which operably controls the redundant means **10,10'**; preventing a decrease in the variable pinch point gap **9,9'**.

25 [0100] In addition to making sure that the a failure of any electro-optical component results in a fail-safe mode, the modulated signal detection means **34**, in the preferred embodiment, is also connected to the fault detection mean **76,77** since certain failures can be detected.

1 [0101] In the preferred embodiment, there is an independent modulated signal detection means 34 for each light guard beam 20, 20' .

[0102] In prior art, Figures 1, 2, 3 & 4, the light guard perimeter was created using two way redirections of the light guard light beams and fixed post
5 mounted to the ground as the starting and stop points for the light guard perimeter. In addition to not providing an adequate distance between the light guard perimeter and the pinch point of concern, this system results in the nuisance of having a floor mount post in the way of the operator 30 .

10 [0103] This invention teaches the idea of using a four way redirection of the light guard light beams and starting and stopping points for the light guard perimeter mounted to the machine. This allows a greater distance between the light guard perimeter and the pinch point of concern. However, while using a floor mount optical repeater node as shown in Figure 34 would provide the greater distance, it would still not solve the problem of the nuisance of
15 having a floor mounted post 96 in the way of the operator.

[0104] This invention includes a solution to this problem, as shown in Figure 35. A remote control means 35 is connected to the sheet stacker 2 and positioned so that the operator 30 has a good visual vantage point for observing the variable pinch point gap 9,9' and the light guard perimeter 21. The
20 remote control means 35 includes deck down enabled button 71 which in the preferred embodiment both allows basic enabling of the decreasing of variable pinch point gap 9,9' and also the activating the light guard control circuit 85 .

[0105] The remote control means 35 is connected to the movable part of the boom 37 which in turn is swivelly attached to or adjacent to the sheet
25 stacker 2, 2' . This give the operator the ability to move the moveable part 37 of boom 36 from the boom in position location 44 to the boom out of position location 45 as shown in Figure 36. From this illustration, we can see how the operator does not have any post in his/her way. Also, there are of-

1 ten other controls on the remote control means **35** that are better adjusted
when the operator is in this boom out of position location **45** .

5 **[0106]** By mounting one of the optical repeating nodes **24'** to the bottom of
the remote control means **35** , which is operably connected to the movable
part of the boom **37**. The resulting configuration provides a completed light
guard perimeter **21** when the boom **36** is at the boom in position location
10 **44**, while also effectively eliminating the possibility of the light guard control
circuit **85** being activated when the remote control means **35** is swiveled to
the boom out of position location **45**. This works well with the design intent
of only letting the operator **30** activate the light guard control circuit **85**
when the boom **36** is in the boom in position location **44** .

[0107] In the preferred embodiment there is also a boom in position sensor
48 , shown in Figure 35, mounted near the elbow of the boom **36** . This al-
lows the basic LCS system control means **15,15'** to make sure the remote
15 control means **35** is properly positioned before allowing the deck down en-
abled button to enable the variable pinch point gap **9,9'** to decrease.

[0108] In the preferred embodiment there is also an operator position sensor
47 , shown in Figure 35 that makes sure the operator **30** is standing in front
of the remote control means **35** as not to be able to activate the light guard
20 control circuit **85** from within the light guard perimeter **21** .

[0109] The light guard means **27** presents the challenge when building full
stacks **6'** because of the need to eventually convey the completed full stacks
6' from within the light guard perimeter **21** to outside the light guard perime-
ter **21** on the conveying sheet removal system **7,7'**. A technique exists
called 'muting' by which the light beam blockage is 'ignored' by the control
25 means when the control means 'thinks' the material is exiting through the
light beams such that the light beam then automatically becomes active after
the control means 'thinks' the material has successfully exited. This tech-
nique is considered inadequate for the sheet stacker **2** application since it is
possible for an operator to enter the light guard perimeter **21** at the same

1 time the full stack **6'** is blocking light beams **20, 20'** resulting in the operator being able to go undetected from the outside to the inside of the light guard perimeter **21** .

5 **[0110]** This!invention solves the problem of transporting the full stacks **6'** from inside to outside the light guard perimeter **21** by configuring the light guard means **27** in a relative fashion to the conveying sheet removal system **7,7'** such that it naturally works with the operators **30** work habits to minimize the impact of needing to press a light guard activation button in order
10 to latch the light guard circuit **85** to an active state after the full stack **6'** has reset the light guard circuit **85** to a deactivated state.

[0111] Figure 37 shows a standard configuring of the light guard means **27** in a relative fashion to the conveying sheet removal system **7** . The important parameter is tie distance **D1 46** which is the distance from the face of the discharge end **4** of the stacking deck **3** where the full stack **6'** is being
15 built to the location where the light beams **20'', 20'''** cross over the conveying sheet removal system **7**. The light beams **20'', 20'''** are the upper and lower beams in the preferred embodiment created by optical repeating nodes **24** positioned at station locations **40,41** shown in Figure 35. In the configuration shown in Figure 37, there is no pallet and/or dunnage inserting system
20 **95** . As a result, the operator **30** is typically required to manually place the pallet **51** and/or dunnage **50** every time the full stack **6'** is transported an adequate distance downstream on to the conveying sheet removal system **7** and before the stacking deck **3** makes the deck down cycle **56''**, referred to in Figure 13 for typical load change cycle **56** sequence. As a result, it is natural for the parameter **D1 46** to be somewhat longer than the length **L 91**
25 of the largest full stack **6'** size so the light guard perimeter **21** is not blocked while full stack **6'** is being built, however, the parameter **D1 46** should allow the full stack **6'** to block and exit the light guard perimeter **21** in short order during the load ejection **56'** allowing the operator **30** to also cross the light guard perimeter **21** and place the pallet **51** and/or dunnage **50** before the as-

1 sociated deck down cycle **56''** begins. As a result, the operator **30** and the
full stack **6'** are both breaking the light guard perimeter at approximately the
same time, and since the operator **30** is in the vicinity of the remote control
means **35** , he/she can easily press a light guard activation button **71** in or-
5 der to latch the light guard circuit **85** to an active state.

[0112] This invention includes a configuration of the light guard means **27** to
allow for a common production line configuration that includes a pallets
and/or dunnage inserter system **95** similar to the one illustrated in Figure 38.
10 When a pallets and/or dunnage inserter system **95** exist, the operator **30** has
the luxury of not having to be present at the discharge end **4** or the stacking
deck **3** during any part of the load change cycle **56** . This is because the
pallet **51** and/or dunnage **50** can be placed on the inserter system **95** during
the time while the full stack **6'** is being built. During the load change cycle
56 the pallets and/or dunnage inserter system **95** automatically indexes the
15 pallet **51** and/or dunnage **50** during the load ejection cycle **56'** in such a way
as to properly position the pallet **51** and/or dunnage **50** to receive the next
full stack **6''** to be created. If the light beams **20''**, **20'''** were to cross over
the conveying sheet removal system **7** at the distance **D1 46** , the operator
30 would be required at the remote control means **35** to press a light guard
20 activation button **71** in order to latch the light guard circuit **85** to an active
state.

[0113] Figures 38 and 39 illustrate the solution to this problem. The light
beams **20''**, **20'''** that cross over the conveying sheet removal system **7** are
moved downstream to the distance **D2 46'** which is the distance from the
face of the discharge end **4** of the stacking deck **3** where the full stack **6'** is
25 being built. The distance **D2 46'** is somewhat longer than twice the longest
length **L 91** of the full stacks **6'** that are planned for production on sheet
stacker **2**. This distance **D2 46'** allows for completed full stack **6'** to be
transported during the load ejection cycle **56'** with its leading edge to stop at
approximate location **P 90** using conveying system control means **92**, which
30

1 is operably connect to a travel limit control means **38** . Since the complete full stack **6'** is still within the light guard perimeter **21**, the latch light guard circuit **85** may remain active and the deck down cycle **56''** can be completed without the need for operator **30** attention.

5 **[0114]** Upon completion of the deck down cycle **56''** , the next new full stack **6''** begins to be built, at which point, the operator has two options for transporting the complete full stack **6'** from inside to outside the light guard perimeter **21**. The conveying system control means **92** may simply wait for the operator **30** to press a load release control **39** at which point the convey-
10 ing system control means **92** which is operably connected to a travel limit control means **38** releases new full stack **6'** for transport downstream. Alternatively, the conveying system control means **92** may be set to a mode that allows the light guarded LCS system control means **15'',15'''** to operably signal the conveying system control means **92** when the deck down cycle
15 **56''** has been completed which then will automatically release new full stack **6'** for transport downstream.

[0115] Figure 39 illustrates in schematic form the functional relationship of conveying system control means **92** . There are many well known ways to implement travel limit control means **38** such that complete full stack **6'**
20 stops at location **P 90** . One common method is to apply a braking section to the rollers integrated into the conveying sheet removal system **7**. Typically, a feedback sensor, full stack at position **P** sensor **93** is connected to conveying system control means **92** . The two optional release signals are also shown in Figure 39. The one coming from the manual activated load release control **39** and the other from light guarded LCS system control means
25 **15'',15'''**, which can monitor the position of the stacking deck **3** . In the preferred embodiment, the conveying system control means **92** would include a selectable mode setting to allow the operator **30** to change release modes depending on the current orders being run in production.

1 [0116] A similar but alternate configuration of the system shown in Figure 38
is shown in Figure 40. The light beams 20'', 20''' that cross over the con-
veying sheet removal system 7 are moved downstream to the distance D3
46'' which is the distance from the face of the discharge end 4 of the stack-
5 ing deck 3 where the full stack 6' is being built. The distance D3 46'' is
substantially longer than the longest length L 91 of the full stacks 6', 6'',
6''' that are planned for production on sheet stacker 2 . !This distance D3
46'' allows a plurality of completed full stack 6', 6'' to be transported and
10 stored within the light guard perimeter 21 making sure the leading leading
edge of full stack 6'!stops at approximate location P 90 using conveying sys-
tem control means 92, which is operably connected to a travel limit control
means 38. Since the complete full stacks 6', 6'' are still within the light
guard perimeter 21, the latch light guard circuit 85 may remain active and
the deck down cycle 56'' can be completed multiple times without the need
15 for operator 30 attention. This is advantageous in production line configura-
tions where there are no pallets 51 and/or dunnage 50 required under full
stacks 6', 6''.
